(Dated: February 19, 2009)

The primordial curvature fluctuation spectrum is reconstructed by the maximum likelihood reconstruction method using the five-year Wilkinson Microwave Anisotropy Probe data of the cosmic microwave background temperature anisotropy. We apply the covariance matrix analysis and decompose the reconstructed spectrum into statistically independent band powers. The prominent peak off a simple power-law spectrum found in our previous analysis turn out to be a 3.3σ deviation. From the statistics of primordial spectra reconstructed from mock observations, the probability that a primordial spectrum including such excess is realized in a power-law model is estimated to be about 2%.

I. INTRODUCTION

The cosmic evolution during the inflationary stage of the early Universe [1, 2, 3, 4] is recorded in the primordial fluctuation spectrum [5, 6, 7], which can be revealed by high-precision observations of the cosmic microwave background (CMB) and large-scale structures. If we found some nontrivial features exceeding a level expected by the cosmic variance after proper analysis of observational errors, we would have to seriously consider its generation mechanism, namely, an inflation model that generates such a nontrivial fluctuation spectrum. This would not only be a challenge to particle-physics model building but also a boon that provides an important clue to high-energy physics. The CMB anisotropy data provided by the Wilkinson Microwave Anisotropy Probe (WMAP) mission [8, 9, 10, 11, 12, 13, 14, 15, 16, 17] is already on the precision level sufficient for such purpose.

There have been persistent controversy on the existence of nontrivial features in the CMB temperature anisotropy spectrum. The angular spectrum of the first-year WMAP data [8, 9, 10, 11, 12] exhibited a sign of a running spectral index, oscillatory behaviors on intermediate scales, and lack of power on large scales, which cannot be explained by a power-law primordial spectrum that is a generic prediction of simplest inflation models. These features may provide clues to unnoticed physics of inflation. Some of these anomalous structures disappeared on the three-year spectrum, but several anomalies are still remaining [14]. To explain these features, a number of inflation models have been proposed [18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33].

To reconstruct the primordial spectrum using CMB anisotropy data without specific prior assumptions about the shape of the primordial spectrum, various observational methods have been proposed [34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46]. Among such attempts, nonparametric methods [47, 48, 49, 50, 51, 52, 53, 54,

55, 56, 57], which can reconstruct the primordial spectrum as a continuous function without any *ad hoc* filtering scale, have a merit for investigating a detailed feature localized in a narrow wave number range. Recently, we reconstructed the primordial spectrum by the cosmic inversion method [47, 48, 49, 50, 51, 52] from the temperature anisotropy spectrum of the five-year WMAP data. The reconstructed spectrum accurately preserved the information of detailed features observed on the angular spectrum. To distinguish possible true signal from the cosmic variance appropriately, we applied the covariance matrix analysis and decomposed the reconstructed spectrum into statistically independent band powers. Although the reconstructed spectrum was basically consistent with a simple power-law spectrum, it exhibited anomalous deviation localized on $\approx 700\text{Mpc}$ scale, which was unfortunately near the border of the wave number domain where accurate reconstruction was possible by the cosmic inversion method. To investigate the possible fine structure, we need to adopt another reconstruction method which can probe a detailed feature of the primordial spectrum in the corresponding wave number range.

The purpose of this work is to revisit the possibility of fine structure in the primordial spectrum. We apply the nonparametric reconstruction method, which is originally developed by Tocchini-Valentini et al.[56, 57], to the five-year WMAP temperature anisotropy spectrum [15] and perform the band-power analysis introduced in our previous work. Because of the arbitrariness of the primordial spectrum, we inevitably incorporate infinite degree of freedom to our analysis, which results in degeneracy among spectral shape and cosmological parameters [55, 58, 59]. However, the fine structure on which we focus in this paper is much narrower than the structure dependent on the conventional cosmological parameters whose characteristic width is principally the inverse of the horizon length at the recombination epoch. As shown in [49], different choices of cosmological parameters affect

only the overall shape and the fine structures of the reconstructed spectrum remain intact. In this paper, we consider the concordance adiabatic Λ CDM model, where the cosmological parameters (except for the ones characterizing the primordial spectrum) are those of the WMAP team's best-fit power-law model [16, 17], and instead focus on the detailed shape of the primordial spectrum.

This paper is organized as follows: In Sec. II, the overview of our analysis is described. In Sec. III, we show the reconstructed primordial power spectrum from the five-year WMAP data and discuss its implication. Finally, Sec. IV is devoted to the conclusion.

II. METHOD

A. Reconstruction formula

We introduce the maximum likelihood reconstruction method¹ to reproduce the primordial power spectrum $P(k)$. Temperature anisotropy is decomposed into the coefficients of spherical harmonics as,

$$\frac{\delta T}{T}(\hat{n}) = \sum_{\ell, m} a_{\ell m} Y_{\ell m}(\hat{n}). \quad (1)$$

A theoretical angular power spectrum C_ℓ is the ensemble average of their norm which is related to $P(k)$ via a radiation transfer function $X_\ell(k)$,

$$C_\ell = \langle |a_{\ell m}|^2 \rangle = \frac{2}{\pi} \int d\ln k \, k^3 P(k) \left(\frac{X_\ell(k)}{2\ell+1} \right)^2. \quad (2)$$

We define the primordial spectrum as the initial spectrum of curvature fluctuation, $P(k) = \langle |\mathcal{R}(0, k)|^2 \rangle$. The probability distribution of a harmonic coefficient for a given $P(k)$ obeys to Gaussian statistics of a complex variable,

$$\mathcal{P}[a_{\ell m}|P(k)] = \frac{1}{\pi C_\ell} \exp\left(-\frac{|a_{\ell m}|^2}{C_\ell}\right) \quad (m \neq 0), \quad (3)$$

$$\mathcal{P}[a_{\ell 0}|P(k)] = \frac{1}{\sqrt{2\pi C_\ell}} \exp\left(-\frac{|a_{\ell 0}|^2}{2C_\ell}\right). \quad (4)$$

Hence the probability of realizing a sky (i.e. a set of harmonic coefficients) is the product of them.

$$\mathcal{P}[\{a_{\ell m}\}|P(k)] = \prod_{\ell, m \geq 0} \mathcal{P}[a_{\ell m}|P(k)]. \quad (5)$$

Defining

$$C_\ell^{obs} \equiv \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} |a_{\ell m}|^2, \quad (6)$$

we find the following log-likelihood function as

$$\mathcal{L} = -\ln \mathcal{P}[\{C_\ell^{obs}\}|P(k)] \quad (7)$$

$$= \sum_{\ell} \frac{(2\ell+1)}{2} \left[\frac{C_\ell^{obs}}{C_\ell} + \ln C_\ell \right] + (const.). \quad (8)$$

If Gaussian distributed measurement noise associates with observed $a_{\ell m}$, the expected mean of the observed angular power spectrum increases due to the noise contribution. Then, the above equations should be modified as

$$C_\ell^{obs} \equiv \frac{1}{2\ell+1} \sum_{m=-\ell}^{\ell} |a_{\ell m}|^2 - N_\ell, \quad (9)$$

and

$$\mathcal{L} = \sum_{\ell} \frac{(2\ell+1)}{2} \left[\frac{C_\ell^{obs} + N_\ell}{C_\ell + N_\ell} + \ln(C_\ell + N_\ell) \right] + (const.). \quad (10)$$

Here we parametrize such noise contribution by N_ℓ . When all-sky information is not available, the above log-likelihood function scales with a sky coverage fraction f_{sky} [60].

In this method, we would like to obtain a power spectrum $P(k)$, which maximizes the above likelihood functional for a given observation. Our master equation consists of a functional derivative of $\mathcal{L}$ with respect to $P(k)$.

$$\frac{\delta \mathcal{L}}{\delta P(k)} = \sum_{\ell} f_{sky} \frac{k^2}{\pi} \frac{|X_\ell(k)|^2}{2\ell+1} \frac{C_\ell - C_\ell^{obs}}{(C_\ell + N_\ell)^2} = 0, \quad (11)$$

where we have used

$$\frac{\delta C_\ell}{\delta P(k)} = \frac{2k^2}{\pi} \frac{|X_\ell(k)|^2}{(2\ell+1)^2}. \quad (12)$$

One can rewrite (11) as

$$\begin{aligned} \sum_{\ell} \frac{k^2 f_{sky}}{\pi (C_\ell + N_\ell)^2} \frac{|X_\ell(k)|^2}{2\ell+1} \int dk' \frac{2k'^2}{\pi} \frac{|X_\ell(k')|^2}{(2\ell+1)^2} P(k') \\ = \sum_{\ell} \frac{k^2 f_{sky}}{\pi (C_\ell + N_\ell)^2} \frac{|X_\ell(k)|^2}{2\ell+1} C_\ell^{obs}. \end{aligned} \quad (13)$$

Discretizing in k' and introducing matrices

$$D_{k\ell} \equiv \frac{k^2 f_{sky}}{\pi (C_\ell + N_\ell)^2} \frac{|X_\ell(k)|^2}{2\ell+1}, \quad (14)$$

$$G_{\ell k'} \equiv \frac{2k'^2}{\pi} \frac{|X_\ell(k')|^2}{(2\ell+1)^2} \Delta k', \quad (15)$$

and vectors $P_{k'} \equiv P(k')$ and C_ℓ^{obs} , (13) can be recast into a matrix equation,

$$\sum_{\ell, k'} D_{k\ell} G_{\ell k'} P_{k'} = \sum_{\ell} D_{k\ell} C_\ell^{obs}. \quad (16)$$

¹ This method was called as *nonparametric reconstruction* by the authors of the preceding works. We compare the result of reconstruction with that by another non-parametric method, namely the cosmic inversion method. Therefore, we call it the maximum likelihood reconstruction method for distinction in this paper.

Although the matrix DG is a square matrix with its dimension equal to the number of discretized points in k , we cannot invert it because the mapping from $P(k)$ to C_ℓ is not one to one. Operation of the matrix G erases two kinds of information in P . One is fine structure in k space, which is smoothed by the convolution with the transfer function. The other is power on the scales of acoustic troughs where the transfer function is almost vanishing. Hence the actual reconstruction suffers a resolution limit and computational noise on specific scales.

According to the Bayes theorem, the conditional probability of $P(k)$ under the condition that each $a_{\ell m}$ takes some observed value reads,

$$\mathcal{P}[P(k)|\{C_\ell^{obs}\}] = \frac{\mathcal{P}[\{C_\ell^{obs}\}|P(k)] \mathcal{P}[P(k)]}{\mathcal{P}[\{C_\ell^{obs}\}]} \quad (17)$$

Here, following the preceding works [56, 57], we assume that $P(k)$ should be a sufficiently smooth function. As the prior probability for $P(k)$, we adopt

$$\mathcal{P}[P(k)] \propto \exp \left[-\epsilon \int dk \frac{1}{2} \left(\frac{dk^3 P(k)}{dk} \right)^2 \right] \equiv e^{-\epsilon \mathcal{R}[P(k)]}, \quad (18)$$

where ϵ is a prior parameter. Then, Eq.(11) is modified to

$$\frac{\delta}{\delta P(k)} \left(\mathcal{L}[P(k)] + \epsilon \mathcal{R}[P(k)] \right) = 0, \quad (19)$$

and the matrix Eq. (16) is modified accordingly to acquire ϵ dependence. As mentioned above, there can be many possible $P(k)$ whose resultant C_ℓ are indistinguishable. Now we have introduced the guiding principle which favors smoother $P(k)$. We can interpret $\mathcal{L}[P(k)] + \epsilon \mathcal{R}[P(k)]$ as the action of a forced oscillator rolling around C_ℓ^{obs} , which assures that the reconstructed $P(k)$ restores the observation. We perform the reconstruction procedure by solving the discretized equation for $P(k)$ as

$$\sum_{\ell, k', k''} \left(D_{k\ell} G_{\ell k'} + \epsilon k^3 {}^t \mathcal{F}_{k k''} \mathcal{F}_{k'' k'} k'^3 \right) P_{k'} = \sum_{\ell} D_{k\ell} C_\ell^{obs}, \quad (20)$$

where the first derivative matrix $\mathcal{F}$ gives the difference between the neighboring elements of an operand over the discretization width and ${}^t \mathcal{F}$ denotes its transposed matrix which acts like $-\frac{d}{dk}$. Practically such discretization results in constraining the first derivatives at both boundaries of the k range concerned, which does not affect the results of reconstruction as long as the reconstruction is performed with sufficiently large buffers around the boundaries.

B. Numerical calculation

We adopt the adiabatic initial condition and fiducial cosmological parameters found by the WMAP team

[17] to calculate the transfer function. Specifically, the cosmological parameters are $h = 0.724$, $\Omega_b = 0.0432$, $\Omega_\Lambda = 0.751$, $\Omega_m = 0.249$, and $\tau = 0.089$, where the distance to the last scattering surface is $d \simeq 1.43 \times 10^4 \text{Mpc}$. The transfer function is calculated by the routines of CMBFAST code [61] with the improved resolution sufficiently for reconstruction of fine structure. Hereafter, we treat $A(k) \equiv k^3 P(k)$ instead of $P(k)$ itself for the comprehensive display purpose and consistency with the common normalization of fluctuation amplitude.

We focus on the angular scales of $30 \lesssim \ell \lesssim 390$ because the actual likelihood evaluation on the largest angular scales is rather complicated and the observational data is noise dominated on the scales of $\ell > 400$. Since C_ℓ mainly depends on the k modes spreading around $k = \ell/d$, the corresponding wave number range is $2.10 \times 10^{-3} \text{Mpc}^{-1} \lesssim k \lesssim 2.73 \times 10^{-2} \text{Mpc}^{-1}$. To avoid the boundary effect, we incorporate the angular spectrum data of $10 \leq \ell \leq 800$ and perform the reconstruction in the much wider range of $1.13 \times 10^{-5} \text{Mpc}^{-1} \lesssim k \lesssim 2.06 \times 10^{-1} \text{Mpc}^{-1}$, which is divided into about 6000 bins.

A part of the matrix D defined in Eq.(14) corresponds to the Fisher matrix for the angular spectrum data. Now we identify the factor, $\frac{(2\ell+1)f_{sky}}{2(C_\ell+N_\ell)^2}$, with the diagonal elements of the Fisher matrix provided by the WMAP team. In the actual Fisher matrix, the diagonal elements have the additional f_{sky} factor and the off-diagonal elements are not vanishing because of the correlation which comes from incompleteness of the observational sky coverage [13]. It is straightforward to incorporate these aspects to our formalism. Substituting the Fisher matrix itself, N^{-1} , to the factor, $\frac{(2\ell+1)f_{sky}}{2(C_\ell+N_\ell)^2}$, we redefine the matrix D as follows:

$$D_{k\ell} \equiv \sum_{\ell'} (N^{-1})_{\ell\ell'} \frac{2k^2}{\pi} \frac{|X_{\ell'}(k)|^2}{(2\ell'+1)^2}. \quad (21)$$

We take account of the entire Fisher matrix in the actual reconstruction. Note also that the matrix D depends on C_ℓ , which is a functional of $A(k)$. When we invert the matrix Eq. (20), we first put C_ℓ^{pl} , which is the angular power spectrum calculated from the best-fit power-law primordial spectrum. Once a solution for $A(k)$ is thereby obtained, we calculate C_ℓ from it and insert the new C_ℓ to the matrix D to repeat the matrix inversion. We thus solve for $A(k)$ iteratively. The solution relaxes to the same form after first iteration because fluctuation around the mean curve of C_ℓ does not seriously affect the matrix D .

Before proceeding to the statistical treatment, let us discuss the criterion for choosing the value of ϵ . Equation (20) indicates that the result of reconstruction depends on the parameter ϵ . As shown in the next section, the reconstructed primordial spectrum has oscillatory modulation. The locations of those peaks are almost independent of ϵ , while the amplitude of the peaks depends on ϵ . For instance, in the preceding works, the value of ϵ is chosen so that the reduced χ^2 value of the re-

stored angular spectrum from the reconstructed primordial spectrum equals unity [56, 57]. Here, it should be noted that a maximum likelihood solution does not necessarily coincide with an underlying primordial spectrum. Indeed, a reconstructed spectrum from a simulated observational angular spectrum based on some power-law primordial spectrum usually has oscillatory modulation, which comes from the cosmic variance, even if we chose the value of ϵ so that the reduced χ^2 value of the restored angular spectrum is unity. In regard to signal detection, however, the most important quantity is not the amplitude itself but the ratio of the signal amplitude to the error magnitude. Robustness of a statistical conclusion against changing the value of ϵ is crucial to our reconstruction scheme. Through the error analysis described in the next subsection, we find that the statistical error of the peak amplitude depends on ϵ in the same manner as the peak amplitude itself and the different choice of ϵ does not seriously affect the statistical significance of the reconstructed features. We set the value of ϵ to $4 \times 10^{-4} \text{Mpc}^{-1}$ so that the power of the reconstructed primordial spectrum is positive on any scale and the reconstructed primordial spectrum fits the result of our previous work in some restricted wave number range, which enables to directly compare the results of two different reconstruction methods. The further discussion is described in the appendix.

C. Monte Carlo simulation

It is theoretically expected that different wave number modes of primordial fluctuation are statistically independent with each other. On the other hand, neighboring wave number modes in the observationally reconstructed primordial spectrum are highly correlated with each other because of the finiteness of the width of the transfer function. Hence in order to perform proper statistical analysis of the reconstructed spectrum, it is important to decompose the reconstructed power spectrum into mutually independent band powers.

For the above purpose, we employ the Monte Carlo method to calculate the covariance matrix of the reconstructed power spectrum. Producing 50000 realizations of a temperature anisotropy spectrum based on the WMAP team's best-fit power-law model whose statistics obey the likelihood function provided by WMAP team with good precision, we obtain 50000 realizations of a reconstructed primordial spectrum. (The detailed prescription of generating mock anisotropy spectra is explained in our previous paper [52].) The covariance matrix of the reconstructed power spectrum is defined by

$$\begin{aligned} K_{ij} &\equiv \frac{1}{N} \sum_{\alpha=1}^N A_{\alpha}(k_i) A_{\alpha}(k_j) - \frac{1}{N} \sum_{\alpha=1}^N A_{\alpha}(k_i) \frac{1}{N} \sum_{\beta=1}^N A_{\beta}(k_j) \\ &\equiv \langle A_{\alpha}(k_i) A_{\alpha}(k_j) \rangle_{\alpha} - \langle A_{\alpha}(k_i) \rangle_{\alpha} \langle A_{\beta}(k_j) \rangle_{\beta}, \end{aligned} \quad (22)$$

where $A_{\alpha}(k_i)$ represents the value of the reconstructed

power spectrum at $k = k_i$ in the α -th realization, and $N = 50000$ as mentioned above.

Significant correlation can be seen between the neighboring bins in the covariance matrix and the characteristic correlation width is $\sim 10/d$ (see Sec. III C). To extract the mutually independent degree of freedom and estimate the reliable error bars, we disentangle this correlation by diagonalizing the covariance matrix. Since K is a real symmetric matrix, it can be diagonalized by a real unitary matrix U , to yield

$$UKU^{\dagger} = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_N) \equiv \Lambda, \quad (23)$$

where λ_i 's are the eigenvalues of K . We find that they are positive definite as they should be, provided that we take N small enough so that neighboring modes are not degenerate with each other. In the present case, we find that if we take $N \lesssim 100$, the covariance matrix is well behaved in the sense that the following procedure is possible with positive definite λ_i and the well-behaved window matrix defined below. In terms of

$$\Lambda^{-1/2} \equiv \text{diag}(\lambda_1^{-1/2}, \lambda_2^{-1/2}, \dots, \lambda_N^{-1/2}), \quad (24)$$

we define inverse square root of K as $K^{-1/2} \equiv U^{\dagger} \Lambda^{-1/2} U$. We also define a window matrix W by

$$W_{ij} = \frac{(K^{-1/2})_{ij}}{\sum_{m=1}^N (K^{-1/2})_{im}}, \quad (25)$$

which satisfies the normalization condition $\sum_{j=1}^N W_{ij} = 1$. Convoluting $A_{\alpha}(k_i)$ with this window function, we define a new statistical variable $S_{\alpha}(k_i)$ as

$$S_{\alpha}(k_i) \equiv \sum_{j=1}^N W_{ij} A_{\alpha}(k_j), \quad (26)$$

whose correlation matrix is diagonal and reads

$$\begin{aligned} \langle S_{\alpha}(k_i) S_{\alpha}(k_j) \rangle_{\alpha} - \langle S_{\alpha}(k_i) \rangle_{\alpha} \langle S_{\beta}(k_j) \rangle_{\beta} \\ = (WK^t W)_{ij} = \left[\sum_{m=1}^N (K^{-1/2})_{im} \right]^{-2} \delta_{ij}, \end{aligned} \quad (27)$$

where ${}^t W$ denotes a transposed matrix.

III. RESULTS OF RECONSTRUCTION

A. Reconstructed primordial spectrum

Figure 1 shows the reconstructed primordial spectrum from the five-year WMAP data and associated 1σ standard errors which correspond to the diagonal elements of the error covariance matrix (see Sec. III C) calculated by Monte Carlo simulation. In this figure, the solid straight line is the best-fit power-law Λ CDM model obtained by

FIG. 1: The reconstruction of the primordial spectrum by the maximum likelihood reconstruction method from the five-year WMAP data. The solid wavy curve is the result of reconstruction and the straight line is the best-fit power-law spectrum. Dotted lines are the standard deviation around the best-fit power law.

FIG. 2: The comparison of the binned five-year WMAP data of $\Delta\ell = 4$ with the anisotropy spectrum restored from the reconstructed primordial spectrum.

the five-year WMAP observations, namely, the power-law spectrum with $A = 2.39 \times 10^{-9}$ and $n_s = 0.961$, where A is the amplitude of curvature perturbation at $k_0 = 0.002\text{Mpc}^{-1}$.

The reconstructed spectrum has the rapid oscillations whose amplitude is about 20% – 30% of the mean value because the reconstruction maps also the cosmic variance on the anisotropy spectrum into wave number space. The modulations of the reconstructed spectrum roughly fit inside the 1σ borders; therefore it is not necessarily required that the inflation model responsible for creation of our Universe should predict such a highly nontrivial spectrum.

The reconstructed spectrum seems consistent with the power-law spectrum on most scales except for the large modulation around the scales of $kd \simeq 120$ (or equivalently $\approx 700\text{Mpc}$). In our previous analysis by the cosmic inversion method, this feature was estimated as about 4σ deviation from a power-law spectrum, however it was located near the border of the wave number domain where accurate reconstruction was possible. In this stage, it seems to be more moderate deviation. To evaluate the statistical significance of the reconstructed spectrum appropriately, we perform band-power decorrelation analysis. The result of our statistical analysis is described in Sec. III C.

B. Restored anisotropy spectrum

Figure 2 illustrates the CMB temperature anisotropy spectrum, which we restore from the reconstructed primordial spectrum by adopting the cosmological parameters of the best-fit power-law model. The effective χ^2 value in the range of $30 \leq \ell \leq 390$ for this restored anisotropy spectrum, which we calculate using the likelihood tool provided by the WMAP team [62], is 327, while that for the best-fit power-law model is 408. Although the degree of fit is improved significantly, it does not have the original statistical meaning because we have incorporated a functional degree of freedom.

The restored anisotropy spectrum traces the fine structure of the observational spectrum fairly well. In particular, it fits the feature of the anomalous peak, which is located around $\ell \simeq 120$. The maximum likelihood reconstruction method reproduces the phase of the observed fine structure more accurately than the cosmic inversion method and, as a result, the location of the anomaly in the reconstructed primordial spectrum has moved to slightly larger wave number ($kd = 125$) than the one evaluated by the cosmic inversion method (see the last paragraph of the appendix). The effective χ^2 value in the range of $100 \leq \ell \leq 140$ is 42, while that for the best-fit power-law model is 61. In the angular spectrum, the anomaly does not look so prominent as in the primordial spectrum because it is located on the steep slope of the first Doppler peak.

C. Band-power analysis

As we can see in the covariance matrix depicted in Fig. 3, neighboring wave number modes strongly correlate. The origin of correlation is the convolution with the transfer function. In particular, mapping the primordial spectrum to C_ℓ erases the information that is responsible for the fine structure whose characteristic scale is below the correlation width $\sim 10/d$. Although our reconstructed primordial spectrum restores the fine structure of the observed angular power spectrum well, the oscillations observed in the raw reconstructed spectrum may

FIG. 3: The error covariance matrix of the reconstructed primordial spectrum, $10^9 A(k)$, calculated by Monte Carlo simulation. The central strip is indicating positive correlation and the surrounding strips are indicating negative correlation. Strong correlation on the largest scales comes from the curvature of the last scattering sphere while error regain on the small scale end of our analysis is due to the domination of measurement error.

FIG. 4: The decorrelated window functions W_{ij} for the intermediate 46 band powers. About 20 modes corresponding to the inner most scales have higher peaks than those to surrounding scales whose strong correlation with neighboring k modes broadens window functions.

not have true statistical meaning.

To extract statistically proper information, we decompose the power spectrum into mutually independent modes. Here, we construct band powers using the window matrix W defined in Sec. II C, which diagonalizes the covariance matrix and gives mutually independent errors. In order for appropriate sampling, we take the

FIG. 5: The band-power decomposition of the primordial spectrum reconstructed from the five-year WMAP data. Each data point indicates the amplitude of diagonalized mode S defined in the text. The horizontal bar indicates the effective width of each window function which depicts the dispersion of the fitted Gaussian distribution.

dimension of the window matrix so that $\Delta kd \simeq 8$. The bands corresponding to the wave number modes which lies between $kd = 30$ and $kd = 390$ are the intermediate 46 bands. Figure 4 shows the window functions for each mode.

Figure 5 is the result of band-power analysis of the five-year WMAP data. In this graph i -th data point indicates the value of

$$S(k_i) = \sum_{j=1}^N W_{ij} A(k_j), \quad (28)$$

and the vertical error bar represents the variance

$$\begin{aligned} & \left[\langle \langle S_\alpha^2(k_i) \rangle \rangle_\alpha - \langle \langle S_\alpha(k_i) \rangle \rangle_\alpha^2 \right]^{1/2} \\ &= \left[\sum_{m=1}^N (K^{-1/2})_{im} \right]^{-1}. \end{aligned} \quad (29)$$

Here, k_i is the location of the peak of the i -th line of the window matrix W_{ij} . The horizontal bar, on the other hand, indicates the width of the window matrix, where the dispersion of the fitted Gaussian is shown. We find their typical width is $\Delta kd \approx 10$ which is basically determined by the width of the transfer function.

The i -th band power depends on the multipole moment on the relevant angular scale of $\ell \sim k_i d$ and also on the surrounding multipoles of $\ell \sim k_i d \pm 5$. Indeed, we found that the statistics of each band-power subject to Gaussian distribution due to the superposition of several multipole moments even though the distribution of simulated C_ℓ is non-Gaussian. By virtue of our band-power analysis, we can also estimate the statistical significance of

FIG. 6: The dependence of reconstruction on the smoothness prior parameter ϵ . From left to right, $\epsilon = 3 \times 10^{-4} \text{Mpc}^{-1}$, $4 \times 10^{-4} \text{Mpc}^{-1}$, and $5 \times 10^{-4} \text{Mpc}^{-1}$.

the reconstructed spectrum itself by evaluating the deviation from the best-fit power-law spectrum at every band simultaneously. We estimated the whole statistical significance of the 46 bands, which correspond to the scales of $30 \lesssim kd \lesssim 390$, and found that, in terms of reduced χ^2 value which is 0.76, the reconstructed spectrum from the five-year WMAP data is (-1.1σ) realization. In our previous work, the statistical significance of the reconstructed spectrum by the cosmic inversion method was estimated to be (-1.5σ) in the wave number range from $kd \simeq 120$ (specifically the band next to the anomalous peak) to $kd \simeq 380$. In the same wave number range, the statistical significance of the reconstructed spectrum by the maximum likelihood reconstruction method is found to be (-1.7σ) . The cumulative deviation from the best-fit power-law spectrum is quite small especially on the scales of $kd \gtrsim 130$.

In our previous analysis, we found a hint of fine structure around $kd \simeq 120$, or equivalently the length scale of $\approx 700 \text{Mpc}$, through the reconstruction by the cosmic inversion method. Here, also by the maximum likelihood reconstruction method, we find the prominent deviation from the best-fit power-law model on the corresponding scale, however, its statistical significance turn out to be a 3.3σ level. Since the statistical distribution of band power is Gaussian, the probability that a band power exhibits 3.3σ or larger excess is $\sim 0.05\%$. Indeed, among 50000 mock samples, we find 31 realizations giving the same or larger excess on the corresponding scale. The probability for realizing a primordial spectrum including such excess is about 2%, which is simply estimated as the product of the one band probability and the number of independent bands. This deviation itself is uncommon but not too rare. The reconstructed spectrum is marginally acceptable as a realization of a power-law spectrum.

FIG. 7: The comparison of the results of two different reconstruction methods. The solid curve is the reconstructed primordial spectrum by the maximum likelihood reconstruction method, where the prior parameter ϵ is set to $4 \times 10^{-4} \text{Mpc}^{-1}$. The dotted curve is that by the cosmic inversion method.

IV. CONCLUSION

We have reconstructed the primordial power spectrum of curvature fluctuation by the maximum likelihood reconstruction method, assuming the absence of isocurvature modes and the best-fit values of cosmological parameters for the power-law ΛCDM model. In a wide range of scales, where the cosmic variance currently dominates over measurement errors ($30 \lesssim kd \lesssim 390$), we can reproduce the fine structures of modulations off a simple power-law with which we can recover the highly oscillatory features observed in C_ℓ .

The statistical significance of the oscillatory structure in the reconstructed power spectrum is difficult to quantify due to the strong correlation among the neighboring wave number modes. We have therefore performed the covariance matrix analysis to calculate the window matrix, which diagonalizes the covariance matrix into statistically independent modes.

In regard to the cumulative deviation (χ^2), the reconstructed spectrum is a common realization of a power-law spectrum. In particular, on the scales of $kd \gtrsim 130$, the best-fit power-law spectrum for the five-year WMAP data fits the reconstructed spectrum slightly excessively well. We have focused on the structure on the scale of $kd \simeq 120$, where previously we found the prominent deviation from the power-law prediction. Although the corresponding band exhibits some deviation from a power-law spectrum, we have found that the feature is marginally consistent with a power-law model.

Finally, we briefly comment on reconstruction from the polarization angular spectrum. The WMAP temperature-polarization cross correlation spectrum exhibits remarkable deviation from the power-law prediction around $\ell \simeq 120$ [62]. The enhancement of (nega-

tive) correlation observed there seems to agree with the anomalous peak found in the reconstructed primordial spectrum in this work, and besides they have apparently similar coherent width. Although the current polarization data is still suffering large measurement errors, the reconstruction from the precise polarization data, which will be available in near future [63], promisingly brings it to a conclusion.

Acknowledgments

We would like to thank K. Ichiki for discussions. We are also grateful to F. Bouchet, D. Spergel for useful comments. This work was partially supported by JSPS Grant-in-Aid for Scientific Research No. 19340054(JY), JSPS-CNRS Bilateral Joint Project “The Early Universe: A Precision Laboratory for High Energy Physics,” and JSPS Core-to-Core Program “International Research Network for Dark Energy.”

APPENDIX: DEPENDENCE ON THE SMOOTHNESS PRIOR PARAMETER

To confirm the robustness of our conclusion, it is important to check its dependence on the prior parameter ϵ . We repeated the statistical analysis described in Sec. II C and Sec. III C with different values of ϵ . As depicted

in Fig. 6, smaller value of ϵ results in larger amplitude of oscillation and then the expected dispersion of the corresponding band power also increases accordingly. The error bars evaluated from the statistics of mock samples contains the contribution of the systematic effect, which comes from the dependence on the value of ϵ . The statistical significance of the anomalous peak concerned in this paper lies around $3.3\sigma \sim 3.5\sigma$ from the best-fit power-law spectrum. In this regard, our reconstruction scheme is not sensitive to ϵ .

Since we are motivated by the result of reconstruction by the cosmic inversion method [52], it is appropriate to choose the value of ϵ , which gives the similar primordial spectrum as that by the cosmic inversion method in the wave number domain where the reconstruction by the cosmic inversion method is accurate. We set the value of ϵ to $4 \times 10^{-4} \text{Mpc}^{-1}$. Figure 7 shows the reconstructed primordial spectra from the five-year WMAP data by the cosmic inversion method and the maximum likelihood reconstruction method. The spectrum reconstructed by the maximum likelihood reconstruction method fits the one by the cosmic inversion method except on the scales where the cosmic inversion method is inaccurate. In this choice of ϵ , we can directly compare the results of the two different reconstruction methods, and besides the power of the reconstructed primordial spectrum by the maximum likelihood reconstruction method is positive on any scale concerned in this paper.
